Impact of zinc supplementation in children with acute diarrhoea in Turkey

P Boran, G Tokuc, E Vagas, S Oktem, M K Gokduman

Objective: Zinc deficiency is prevalent in children in developing countries. Supplemental zinc provides therapeutic benefits in diarrhoea. Our aim was to evaluate the effect of daily zinc supplementation for 14 days on diarrhoea duration, severity, and morbidity in children.

Methods: In a randomised, open label non-placebo controlled trial, we assessed the efficacy of providing zinc sulfate to 6–60 month old children with acute diarrhoea for 2 weeks followed by 3 months of morbidity surveillance. Children were randomly assigned to zinc (n = 150) and control (n = 130) groups and received 15–30 mg elemental zinc daily.

Results: Supplemented children had significantly improved plasma zinc levels by day 14 of therapy. Zinc deficiency was observed in 2.6% of the treatment and 3.3% of the control group. The mean duration of diarrhoea after starting supplementation was 3.02 ± 2 days in the zinc group and 3.67 ± 3.2 days in the control group. There was no significant difference in diarrhoea duration by treatment group (p > 0.05). The number of stools after starting supplementation was 5.8 ± 3.7 and 5.1 ± 3.9 on day 1, 2.9 ± 1.6 and 3.0 ± 2.2 on day 2, and 1.8 ± 1.1 and 1.6 ± 0.9 on day 3 in the zinc and control groups, respectively. There was no significant difference in diarrhoea severity by treatment group (p > 0.05). No significant effect was found on the incidence and prevalence of diarrhoea in the zinc compared with the control group.

Conclusion: Our data indicate that supplementing children with acute diarrhoea in Turkey with 3 RDA of elemental zinc for 14 days improved neither diarrhoea duration nor severity despite significant increments in plasma zinc.

Worldwide, diarrhoeal diseases are a leading cause of paediatric morbidity and mortality, with 1.5 billion episodes and 1.5–2.5 million deaths estimated to occur annually among children below 5 years of age. In Turkey, approximately 30,000 deaths occurred in 1986, but the estimated rate had declined to 10,000/year by 1992. Although the total number of deaths has been reduced substantially, diarrhoea still accounts for about 6% of all deaths in children below 5 years of age.

In 1992, the Center for Disease Control (CDC) prepared the first national guidelines for managing childhood diarrhoea and further data have since emerged regarding diarrhoea treatment, including the importance of zinc supplementation. Multiple reports, all from the developing countries, have linked diarrhoea and abnormal zinc status, including increased stool zinc loss, negative zinc balance, and reduced tissue levels of zinc. It is thought that zinc deficiency might play a role in childhood diarrhoea and zinc supplementation might be of benefit either for improving outcomes or as prophylaxis against diarrhoea. Possible mechanisms for the effect of zinc treatment on diarrhoea include improved absorption of water and electrolytes by the intestine, faster regeneration of gut epithelium, increased levels of enterocyte brush border enzymes, and enhanced immune response, leading to early clearance of diarrhoeal pathogens from the intestine.

In the randomised controlled trials of zinc supplementation that evaluated prevention of diarrhoea, significantly lower incidences of diarrhoea occurred in the zinc groups than in the controls. A pooled analysis that includes most of these trials revealed 18% less diarrhoea in the zinc supplemented children. Furthermore, zinc supplements given for 14 days during and after diarrhoea can reduce the incidence of diarrhoea in the subsequent 2–3 months. The World Health Organization (WHO) has recommended that zinc is used in the treatment of persistent diarrhoea, which means trials on persistent diarrhoea are no longer appropriate.

We aimed to evaluate the impact of zinc supplementation on acute diarrhoea severity and duration, and conduct morbidity surveillance for 3 months after supplementation was given.

METHODS
We carried out a home based, prospective, randomised, open label, non-placebo controlled trial in 280 children aged 6–60 months from April 2004 to January 2005. The study protocol was approved by the respective institutional ethics committees at the Dr. Lutfi Kirdar Kartal Research and Training Hospital, Istanbul. Eligible children were included after informed consent was received from at least one of the parents.

Children with acute diarrhoea of <14 days pre-enrolment duration were recruited for the study from the paediatric emergency and outpatient clinic. Exclusion criteria included refusal of consent, malnutrition, medical conditions requiring hospitalisation, and having received anti-diarrhoea medications and antibiotics. Children were randomly assigned to one of two groups. Block randomisation was carried out using eight numbers in each block to ensure that equal numbers of patients entered each group after every eight patients. diarrhoea was managed according to WHO guidelines. The study group received 3 RDA of zinc in a syrup once daily (15 mg zinc for 6–12 month old children

Abbreviations: CDC, Center for Disease Control; RDA, recommended dietary allowance; WHO, World Health Organization
and 30 mg for 12–60 month old children) as zinc sulfate for a total of 14 days; the control group received oral rehydration salts solution only. The RDA is 5 mg elemental zinc/day for infants and 10 mg/day for children 1–4 years old. Any vomiting or nausea, other possible side effects, and the amount of supplement taken was recorded by the mother. Children were examined by the physician each day at the hospital until the diarrhoea episode had ceased and were then followed up every 7 days by phone call. During each hospital visit, the study physician asked about the child’s health, the number and characteristics of all stools passed, and the use of the supplement each day since the last visit. Children were referred to the study physician for re-examination if they had recurrent diarrhoea or evidence of other infection during the study period.

Nutritional status was assessed using weight for height, height for age, and weight for age z scores. The values for each nutritional index were converted into standard deviation (z) scores according to the 2000 CDC growth charts. Apparently healthy children who recovered from the diarrhoea episode within 2 weeks of supplementation had effects on morbidity assessed by surveillance for a subsequent 3 months without further supplementation.

At enrolment and on day 15, non-fasting venous blood was drawn into zinc-free heparinised tubes between 9 am and 4 pm. Plasma was stored at −20°C until analysis. Plasma specimens were analysed for zinc using an atomic absorption spectrophotometer technique.22

Diarrhoea was defined as three or more loose stools in a 24 h period. An episode of diarrhoea was defined as at least 1 day of diarrhoea, with the final day of the episode being the last day meeting the diarrhoea definition followed by at least 48 h without diarrhoea. Two consecutive days free from disease were regarded as resolution of previous diarrhoeal illness. Relapse was defined as a new episode of diarrhoea during the study period. Serum zinc concentrations were considered low if they were <60 µg/dl. The trial outcomes included diarrhoea duration, severity, incidence, and prevalence (the number of new episodes of the illness and number of days with the illness, respectively, per total days of observation).

Based on information from previous studies,22 a sample size of 130 children per group was calculated to be adequate to detect a 35% difference in the duration of the current episode of diarrhoea after starting the treatment. Statistical analyses were completed by using SPSS 10.0 and significance was set at 5%. Analysis of variance and χ² tests were used to assess differences among groups. The possible covariates included age, sex, nutritional status, initial stool frequency, and initial plasma zinc concentration. We estimated the therapeutic effect of zinc on the incidence and prevalence of diarrhoea episodes by calculating odds ratios and 95% confidence intervals. The odds ratios were obtained by using logistic regression.

RESULTS

The children in the two groups were comparable as regards baseline characteristics including age, child feeding practices, nutritional status, maternal literacy, family size, and socioeconomic characteristics. Responses to the socioeconomic survey indicated that about 90% of the mothers were housekeepers, 90% of the mothers were between 18 and 35 years of age, family income was above the minimum wage in 60%, and family size was under five in 84%. No significant differences were noted between the two groups (p>0.05). Five patients in the zinc group and 10 patients in the control group were lost to follow up and the final analysis was performed in the remaining patients. Table 1 details the admission characteristics of the two groups.

The mean plasma zinc levels at baseline and at the end of the study were 109.6 ± 22.6 and 132.7 ± 35.8 µg/dl in the zinc group and 102.9 ± 32.3 and 101.8 ± 23.7 µg/dl in the control group, respectively. In the zinc group 2.6% of the children had a plasma zinc concentration below 60 µg/dl, and in the control group 3.3% of the children had a plasma zinc concentration below 60 µg/dl. The plasma zinc concentration was significantly higher at the end of the study in the zinc supplemented group (p<0.05). The difference in plasma zinc between the end of study and baseline concentrations was also substantially higher in the zinc group as compared with the control group (p<0.05).

Five children (4.3%), all in the zinc group, reported vomiting each day immediately after the supplement was given during the first week of supplementation. If the patient vomited within 10 min after receiving the supplementation, the dose was repeated. The reported data revealed no side effects other than vomiting.

The mean duration of diarrhoea after starting the supplement was 3.02 ± 2 days in the zinc group and 3.67 ± 3.2 days in the control group. There was no significant difference in diarrhoea duration by treatment group (p>0.05). Evaluation of the outcomes for the subgroup with low admission plasma zinc levels (<60 µg/dl), who also had the greatest number of stools (>10 stools per day v 6–9 and 3–5 stools per day), did not reveal any significant differences (p>0.05).

The number of stools after starting the supplement was 5.8 ± 3.7 and 5.1 ± 3.9 on day 1, 2.9 ± 1.6 and 3.0 ± 2.2 on day 2, and 1.8 ± 1.1 and 1.6 ± 0.9 on day 3 in the zinc and control groups, respectively. There was no significant difference in diarrhoea severity by treatment group (p>0.05).

Approximately one fifth of the children in the zinc (30/150) and control (25/130) groups in this study no longer had diarrhoea as early as day 1. During the follow-up period, 14.5% of the children in the zinc group and 13.5% of the children in the control group had a relapse of diarrhoea. No significant effects was found for the incidence (odds ratio (OR): 1.34; 95% confidence interval (CI): 0.68 to 2.65) or prevalence of diarrhoea (OR: 1.06; 95% CI: 0.92 to 1.22) in the zinc group as compared with the control group.

DISCUSSION

Zinc deficiency, which is prevalent in children in developing countries, places children at increased risk of infectious
diseases in those regions. During supplementation trials with zinc, the major effect has been shown to be on diarrhoea related morbidity. Although WHO has recommended that zinc is used in the treatment of persistent diarrhoea, more information is needed on the use of zinc supplementation in acute diarrhoea in different settings. In addition to the preventive trials in which zinc was given on a routine, usually daily, basis for an extended period of time, in other trials zinc was provided as an adjunct to therapy for acute and persistent diarrhoea. The preventive trials are consistent in showing that zinc supplemented children have lower rates of diarrhoea than control children. The trials evaluating the therapeutic effects of zinc for diarrhoea demonstrate that the zinc supplemented children have episodes of shorter duration, a lower number of stools or smaller stool volume, and a reduction in treatment failure or death. In this study, most children were able to adequately absorb oral zinc sulfate with an increase in plasma levels. Evidence that the zinc was successfully absorbed is provided by the plasma concentration of zinc which by day 15 of therapy had risen significantly in the zinc supplemented groups. However, in contrast to previous studies, our data suggest that supplementing healthy children with acute diarrhoea for 14 days neither improved diarrhoea recovery nor had an impact on morbidity during the subsequent 3 months without further supplementation. It must be recognised, however, that this trial was conducted in ambulatory, apparently healthy children without malnutrition, who had not been hospitalised. Previous trials were conducted with malnourished children with more severe diarrhoea and living in typical developing country settings where the prevalence of subclinical zinc deficiency is approximately 80%. The trials also selected moderately or severely undernourished children whose growth was stunted. In addition, there may have been differences in therapeutic approach such as supplementation with zinc for longer periods and additional supplementation with multivitamins; the beneficial effect shown in the trials could be the result of a synergistic effect caused by multivitamin supplementation.

What is already known on this topic

- Zinc deficiency, a prevalent condition in children in developing countries, places these children at increased risk of infectious diseases.
- Supplementation trials with zinc have shown zinc has a major effect on diarrhoea related morbidity.
- Zinc supplements given for 14 days during and after diarrhoea reduce the duration and severity of treated diarrhoea episodes and can reduce the incidence of diarrhoea in the subsequent 2–3 months.

What this study adds

- Supplementing healthy children with acute diarrhoea in Turkey with 3 RDA/day of elemental zinc during 14 days neither improved diarrhoea recovery nor morbidity, despite significant increments in plasma zinc concentrations.
- Specific recommendations regarding the use of zinc supplementation in acute diarrhoea should await additional population based studies assessing the role of zinc supplementation in the treatment of children with acute diarrhoea.

Previous analyses have shown that zinc supplementation has a greater effect in children with lower plasma zinc concentrations. The low prevalence of zinc deficiency in our study could be a reasonable explanation for the failure of zinc therapy. It is likely that initial zinc status influences the response to therapy and the benefits of zinc supplementation may be limited to individuals or populations with pre-existing zinc deficiency. In the present study, data analysis did not reveal any significant differences (p>0.05) between a low plasma zinc group and a normal zinc group. The differences in diarrhoeal duration and severity were not statistically significant, possibly because the small sample size of the subgroup with low zinc levels was too small to detect a statistically significant difference.

Furthermore, this low percentage of zinc deficiency found in the present study could be because the mean duration of diarrhoea (3.02±2 days) after starting the supplement is too short time for increased intestinal losses of zinc to cause zinc deficiency in a healthy child.

Approximately one fifth of the children in the zinc group (30/150) in our study no longer had diarrhoea as early as the first day of treatment. This rapid recovery from diarrhoea on the first day of intervention complicates interpretation of the results because it seems unlikely that zinc could have influenced clinical outcomes so quickly. Indeed, a previous supplementation trial among children with acute diarrhoea showed that there was only a small, non-significant reduction in the risk of continuing diarrhoea during the first three days of zinc treatment, whereas there was a statistically significant 38% reduction in the risk of ongoing illness in zinc treated children after the third day of therapy.

Following the recommendations of the pharmaceutical industry, zinc supplements are already widely used for outpatients with diarrhoea and as an adjunct therapy in acute diarrhoea. Well-nourished children with normal serum level of zinc may experience delayed adverse effects following zinc supplementation. Iron deficiency anaemia is the most common nutritional deficiency in the developing world, particularly in preschool children. A significant interaction of zinc absorption with copper and iron has been described and zinc supplementation alone may aggravate the deficiencies of other minerals; measures of iron and copper status would have been helpful in this study, but there were none. Furthermore, Ruel et al found that both the incidence and prevalence of respiratory infection were higher in children who received zinc supplementation. Schlesinger et al have shown that zinc supplementation inhibits phagocytic and fungicidal activity in malnourished infants. In studies assessing the effect of zinc supplementation on the developmental levels of infants, Hamadani et al found that the mental development index scores of a zinc treated group were slightly but significantly lower than those of a placebo group and suggested zinc supplementation in pregnant...
mothers had a negative effect on the mental development of their children at 13 months of age. 32

In conclusion, our data indicate that supplementing children with acute diarrhoea in Turkey with 3 RDA/day of elemental zinc for 14 days improved neither diarrhoea recovery nor morbidity, despite significant increments in plasma zinc concentrations. We believe that the adverse effects of zinc supplementation should be weighed against the beneficial effect of zinc in reducing diarrhoea. Specific recommendations regarding the use of zinc supplementation in acute diarrhoea should await additional population based studies assessing the role of zinc supplementation in the treatment of children with acute diarrhoea.
